Abstract: The high-order harmonic generation in a polar medium (a medium with a permanent dipole moment) driven by a chirped few-cycle laser pulse is investigated via numerically solving the nonlinear Bloch equations or Maxwell-Bloch equations if taking the propagation effect into account. The time-frequency characteristic of the harmonic is analyzed by means of the wavelet transform of induced time-dependent dipole moment. The simulation results demonstrate that, the harmonic cutoff energy can be dramatically extended as a result of the existence of the permanent dipole moment, and the quantum trajectory number for plateau harmonics can be largely reduced due to the introduce of chirps. Correspondingly, an attosecond pulse pair (APP) can be generated. Moreover, the propagation effect can make the APP's intensity enhanced by one order at a suitable propagation distance, and the latter can be modulated by changing the medium's density.

1. Introduction

Femtosecond laser technology has obtained rapid development over the past decades, and it provides us important tools to study the strong-field physics as well as the ultrafast phenomena. People can observe the ultra-fast dynamic chemical reaction process using the femtosecond technology, such as, the breaking and restructuring of the chemical bond [1] and the vibrations of an atom or a molecule [2]. However, if we want to observe further faster physical phenomena, such as electron motion, the sub-femtosecond or attosecond pulse should be used [3]. In recent decades, one important and effective method to generate an attosecond laser pulse is the Fourier synthesis to the high-order harmonics. Krausz's team has first obtained the sub-femtosecond pulse output (650 as) experimentally in 2002 [4]. From then on, two milestones are obtained: one is that Krausz's team [4] obtained an 80 as pulse by utilizing a 3.3 fs driving laser pulse, which broke the limit of 100 as, and the other is Chang's group composed a 67 as single isolated attosecond pulse from an extreme UV supercontinuum [5].

As for the high-order harmonic generation (HHG), it is first proposed by Shore and Knight in 1987 [6], and subsequently, observed experimentally by McPherson [7] and Farray [8]. Its intuitive physical mechanism can be summarized as a *three-step* model proposed by Corkum first [9] and developed by Lewenstein *et al.* later [10]: first, electrons are liberated from the parent ion via tunneling ionization, then they move away and acquire energy from the laser field, finally small part of them may return back to the parent ion and recombine to the ground state with a harmonic photon emitted. The whole HHG spectrum has a unique character: the first few harmonics decay exponentially rapidly followed by a plateau in which the harmonic intensity varies weakly with order, and eventually an abrupt cut-off occurs [11]. Later, people found that HHG can also occur with no electron ionization. For a two-level atomic system, if the driving laser field is not so strong and the frequency is much less than the atomic energy level transition frequency, a HHG process can be demonstrated and the corresponding HHG spectrum also process a long generic plateau and a clear cutoff [12–15]. This kind of HHG has no connection with the above mentioned *three-step* model, and its origin is clarified by Gauthey *et al.* [15] as a link to the rapid level crossing at each half-cycle of the laser period. The cutoff position analytically presented under a driven two-level model is in a good agreement with the numerical simulation result. Faria *et al.* [16] extended this two-level model with an analogous *three-step* model to explain the harmonic generation process: a population transfer occurs from the field-dressed adiabatic lower state to the upper state at level crossing time, then the system acquires energy from the laser field, finally decays back to the lower state and radiates a harmonic photon with the energy equaling to the transient transition energy separation.

Fourier transform to the harmonics within the plateau or the cut-off part of the spectrum via referring filtering or other technology is a routine tool to get an attosecond pulse train

(APT) or an isolated attosecond pulse (IAP) generated. Quantum control schemes for obtaining high quality IAP or APT have been demonstrated widely, such as polarization gating [9, 17], nonlinear chirp [18], two-color driving laser pulse [19], or some kind of combination of these methods [20], etc.. In the driven two-level regime, the two-color laser pulse [21–23] has been demonstrated, and it is found that the plateau can be extended. In addition, if the target is polar medium, the plateau can be even extended to X-ray range [24]. Moreover, if a hyperbolic tangent chirped few-cycle laser pulse is used to drive a two-level quantum well, an ultra-broad super-continuum can be obtained to synthesize an isolated terahertz pulse [25].

Actually, almost all the studies about HHG based on the driven two-level model just considered the single-particle-response, namely, the two-level system is only one atom, one molecule or one quantum well, etc. However, there are thousands of particles, the laser pulse and generated harmonics will propagate through the medium in the real experiment. As we know, in the ionization regime, if the driving pulse and the harmonic have the same phase velocity as they travel through the medium, the harmonic signal will achieve significant increase [33]. Many studies based on the driven two-level model with dense medium also have been done [34–38], however, their focus is mainly concentrated on the modulation of the laser pulse during the propagation process. Therefore, the macroscopic propagation process will be investigated in this paper and is expected to enhance the harmonic signal.

Based on the above, therefore, this paper proposes that one can control the matter and the driving laser pulse at the same time. The plateau extension is expected with the help of permanent dipole moment, meanwhile, coherent enhancement for the HHG spectrum is expected by modulating the laser pulse with a chirp, and the medium's macro aspect is expected to enhance the harmonic signal.

2. Theoretical models and methods

For the two cases of propagation considered or not, both the simulation model and the numerical solving method are different. In simple terms, here, non-propagation case need to solve the nonlinear Bloch equations by Runge-Kutta method and the propagation case need to solve the Maxwell-Bloch equations by finite-difference time-domain (FDTD) method. The two models and their corresponding solving methods will be introduced separately.

First for the non-propagation case. Consider a two-level system where $|1\rangle$ and $|2\rangle$ represent the ground and excited states with the energy separation ω_0 [Atomic units (a.u.) are used in this paper, unless otherwise mentioned]. Within this picture, the time-dependent wave function is

$$|\Psi(t)\rangle = c_1(t)|1\rangle + c_2(t)|2\rangle, \quad (1)$$

where $c_i(t) = \langle i|\Psi(t)\rangle$ ($i = 1, 2$) denotes the overlap of the total wave function with the i^{th} state.

A semi-classical model is adopted in which the quantum system interacts with the classical laser field. The total Hamiltonian describing the interaction of the laser field with the two-level system which has permanent dipole moments is [24]

$$H = H_0 + V = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} - E(t) \begin{pmatrix} \mu_{11} & \mu_{12} \\ \mu_{21} & \mu_{22} \end{pmatrix}, \quad (2)$$

where μ_{ij} are the dipole moment matrix elements, and $E_1 = -\frac{1}{2}\omega_0$, $E_2 = \frac{1}{2}\omega_0$. The linearly polarized Gaussian pulse is used to drive the system and the laser field is given by expression of

$$E(t) = E_0 \exp \left[-4 \ln 2 (t/\tau)^2 \right] \cos [\omega_L t + \varphi(t)], \quad (3)$$

where E_0 is the field amplitude, τ is the duration (full width at half maximum, FWHM), ω_L is the field angular frequency, and $\varphi(t)$ is the time-dependent carrier envelope phase.

Finally, the system dynamics can be described by the following nonlinear Bloch equations:

$$\partial_t u(t) = \omega_0 v(t) + 2\xi \Omega(t) v(t), \quad (4)$$

$$\partial_t v(t) = -\omega_0 u(t) + 2\Omega(t) w(t) - 2\xi \Omega(t) u(t), \quad (5)$$

$$\partial_t w(t) = -2\Omega(t) v(t). \quad (6)$$

Where, $u(t)$ and $v(t)$ are the mean real and imaginary parts of polarization, respectively, $w(t)$ is the mean population difference. $\Omega(t) = -\vec{\mu}_{21} \cdot \vec{E}(t) = \Omega_0/E_0 \cdot E(t)$ is the Rabi frequency of the incident laser field with peak value of $\Omega_0 = -\mu_{21}E_0$, $\xi = (\mu_{22} - \mu_{11})/2\mu_{21}$ is a dimensionless parameter which characterizes the permanent dipole moment. In the two-level model, the main observable of interest is $u(t)$, which leads to the coherent part of the light spectrum by Fourier transform

$$P(\omega) = |\int dt \exp(i\omega t) \bar{N} u(t)|^2. \quad (7)$$

Where \bar{N} is density of the medium, it is introduced here for the consistency with propagation situation discussed later. It is chosen as $\bar{N} = 7.5 \times 10^{24} \text{m}^{-3}$ for both the propagation and non-propagation cases. The system of evolution Eqs. (4)–(6) can be solved numerically without making rotating-wave approximation by means of a fourth-order Runge-Kutta method. The Fourier transform is performed using the Fast Fourier transform algorithm.

Moreover, the time-frequency analysis is performed to the high-order harmonic generation by using the wavelet transform to the induced dipole moment $u(t)$ in order to investigate the temporal structures of HHG spectrum,

$$A_\omega(t, \omega) = \int \bar{N} u(t') \sqrt{\omega} W[\omega(t-t')] dt', \quad (8)$$

where $W(x)$ is the window function (also called the mother wavelet function) which is given here by the form of Morlet wavelet [25, 39–41]

$$W(x) = \sqrt{\frac{1}{\tau_{\text{wav}}}} e^{ix} e^{-x^2/2\tau_{\text{wav}}^2}, \quad (9)$$

t and ω denote the time and harmonic frequency at which the window function is centered. The envelope width τ_{wav} of the wavelet is set to 6.0 in our calculations.

As for the propagation case, the Maxwell-Bloch equations should be numerically solved. Now, propagation of a linearly polarized short laser pulse along the z axis to an input interface of the two-level medium at $z = L_1$ is considered. Initially the pulse propagates in the vacuum of free space, then it penetrates into the medium with some reflects, the penetrating part propagates through the medium and finally exits again into the vacuum through the output interface at $z = L_2$ [34]. If the laser field is assumed to polarize along the x axis, then the Maxwell-Bloch equations would take the form of

$$\begin{aligned} \partial_t H_y(z, t) &= -\frac{1}{\mu_0} \partial_z E_x(z, t), \\ \partial_t E_x(z, t) &= -\frac{1}{\epsilon_0} \partial_z H_y(z, t) - \frac{1}{\epsilon_0} \partial_t P_x(z, t), \\ \partial_t u(z, t) &= \omega_0 v(z, t) + 2\xi \Omega(z, t) v(z, t) - u(z, t)/T_2, \\ \partial_t v(z, t) &= -\omega_0 u(z, t) + 2\Omega(z, t) w(z, t) - 2\xi \Omega(z, t) u(z, t) - v(z, t)/T_2, \\ \partial_t w(z, t) &= -2\Omega(z, t) v(z, t) - [w(z, t) - w_0]/T_1. \end{aligned} \quad (10)$$

Here E_x, H_y is the laser pulse electric and magnetic field, respectively. μ_0 and ϵ_0 are the vacuum permeability and vacuum permittivity, respectively. w_0 is the initial population difference. Maxwell equations are united with the Bloch equations here, and the physical quantities are not only dependent on the time but also dependent on the propagation distance, z . Here the relaxation time of the two-level medium is considered, where T_1 is the excited-state lifetime and T_2 is the dephasing time. It is noted that, for the non-propagation case, the relaxation time are not considered because of that they are much longer than the laser-matter interaction time. P_x is the macroscopic nonlinear polarization, and is given for two-level system as expression of [36]

$$P_x = \bar{N} \text{tr}(\vec{\mu} \vec{\rho}) = \bar{N}(\mu_{11}\rho_{11} + \mu_{22}\rho_{22} + \mu_{12}\rho_{12} + \mu_{21}\rho_{21}) \quad (11)$$

where \bar{N} is the density of the medium, ρ_{ij} ($i, j = 1, 2$) is the density matrix element for the two-level system. If the system is closed (i.e., the system has no energy exchange with the outside environment), P_x can be further expressed as

$$P_x = \bar{N}\mu_{21}u + \bar{N}\xi\mu_{21}w + \bar{N}(\mu_{11} + \mu_{22})/2. \quad (12)$$

Eq. (10) can be solved using Yee's leap-frog FDTD discretization scheme [42] with the iterative predictor-corrector method [35]. Mur absorbing boundary conditions [43] were incorporated with FDTD discretization which can avoid the unphysical reflection from the finite calculation boundaries. Here, the initial pulse condition is given as

$$\begin{aligned} E_x(z, t=0) &= E_0 \exp\left[-4 \ln 2 \left(\frac{z-z_0}{c\tau}\right)^2\right] \cos[\omega_L(z-z_0)/c + \varphi(t)], \\ H_y(z, t=0) &= \sqrt{\epsilon_0/\mu_0} E_x(z, t=0), \end{aligned} \quad (13)$$

where c is the light velocity in the vacuum. The choice of z_0 can ensure that the pulse penetrates negligibly into the medium at $t = 0$. In our calculations z_0 is set to be $15 \mu\text{m}$.

In the following calculations, unless indicated, the following parameter values are adopted. The two-level system is assumed initially in its ground state with an energy separation $\omega_0 = 0.30$ a.u., thus $u(0) = v(0) = 0$, and $w(0) = -1$. The dipole moment matrix element is $\mu_{21} = 1.0 \times 10^{-29}$ Asm (corresponds to 1.18 a.u.). As for the driving laser pulse, its center frequency is $\omega_L = 0.056$ a.u. corresponding to a wavelength of 814 nm, its pulse duration is $\tau = 2T$ (about 5.43 fs, T is the laser period) and its peak Rabi frequency is $\Omega_0 = 0.30$ a.u.. For the propagation situation, the relaxation time of the two-level medium are: $T_1 = 1.0 \times 10^{-12}$ s, $T_2 = 0.5 \times 10^{-12}$ s [34].

3. Results and discussions

3.1. non-propagation situation

First, as generally done [14–16, 19, 21–25], the propagation effect is temporally neglected and only the single-particle-response is considered.

It has been well clarified that, as for a two-level atomic system, the occurrence of HHG is attributed to the rapid level crossing mechanism between the two field-dressed adiabatic states [15]. In the adiabatic basis, the Hamiltonian is diagonalized via a unitary transformation as,

$$\tilde{H} = \hat{U} H \hat{U}^\dagger = \begin{pmatrix} \epsilon_- & 0 \\ 0 & \epsilon_+ \end{pmatrix}, \quad (14)$$

with the field-dressed level energies [24]

$$\varepsilon_{\pm} = \frac{1}{2} \left(-\frac{\mu_{11} + \mu_{22}}{\mu_{21}} \Omega(t) \pm \sqrt{[2\xi\Omega(t) - \omega_0]^2 + [2\Omega(t)]^2} \right). \quad (15)$$

and the frequency of harmonic emitted at time t is determined by the transient energy separation of these two states,

$$\omega = \varepsilon_+ - \varepsilon_- = \sqrt{[2\xi\Omega(t) - \omega_0]^2 + [2\Omega(t)]^2} = N\omega_L. \quad (16)$$

Where, N is the harmonic order. Formula (16) clearly indicates that the harmonic frequency varies over time and would have a maximum value ω_{\max} with a cutoff order N_{\max} at time t_{\max} which can be found with the help of the $\omega - t$ plot curve.

Fig. 1. HHG spectra of a laser-driven two-level system with (a) $\mu_{11} = \mu_{22} = 0$ ($\xi = 0$) (b) $\mu_{11} = -4\mu_{21}, \mu_{22} = 4\mu_{21}$ ($\xi = 4$), (c) $\mu_{11} = 4\mu_{21}, \mu_{22} = -4\mu_{21}$ ($\xi = -4$). (d), (e) and (f) show their corresponding time-dependent eigenvalues of the two dressed states ε_+ and ε_- . (g), (h) and (i) show their corresponding time-frequency spectra via wavelet transforms, while the lower panel displays the time-dependent energy separation between the two dressed states $\varepsilon_+ - \varepsilon_-$ (the harmonic energy predicted by two-level model) and the absolute amplitude of laser field. Parameters for this laser pulse are: central frequency $\omega_L = 0.056$ a.u., duration $\tau = 5.43$ fs, and peak Rabi frequency $\Omega_0 = 0.30$ a.u..

If the two-level system has no permanent dipole moment existing, that is, $\xi = 0$, and the driving laser pulse is not chirped, the numerical obtained HHG spectrum is shown in Fig. 1(a). It possesses the generic characteristics of a HHG spectrum: a plateau and a clear cutoff. The cutoff order is 11, which agree well with the predicted value N_{\max} [seen in lower panel of Fig. 1(g)].

3.1.1. polar medium

Now, if the polar medium is considered, there will be a permanent dipole moment existing. As shown in Fig. 1(b) and 1(c), the corresponding HHG spectrum will change significantly,

even though the other laser and medium parameters remain unchanged. For example, if the permanent dipole moment is $\mu_{11} = -4\mu_{21}$, $\mu_{11} = 4\mu_{21}$ ($\xi = 4$) as shown in the middle column of Fig. 1, the cutoff harmonic order is extended to be about 40th, which also agree well with the prediction value N_{\max} [seen in lower panel of Fig. 1(h)]. If the permanent dipole moment is large enough [e.g., $\mu_{11} = 0$, $\mu_{11} = 16\mu_{21}$ ($\xi = 8$)], the cutoff order can be further extended to the soft X-ray range, which would provide a possibility to generate a much shorter IAP or APT by synthesizing much more harmonics. It is found from the comparison between the right two columns of Fig. 1 that, the harmonic generation process is sensitive to the direction of initial permanent dipole moment: for negative ξ (here we call it the negative direction, seen in the right column), the cutoff harmonic is emitted only at laser field peak time, while for positive ξ (the positive direction, seen in the middle column), it is emitted at both sides of the peak with about $0.5T$ interval to the peak time. In addition, Figs. 1(g), 1(h) and 1(i) clearly demonstrate that the time-frequency HHG spectrum shares the same shape with the laser pulse absolute amplitude [25]. Even though there's little difference existing for the case of positive initial permanent dipole moment (positive ξ), but at least the minimum time and peak time of the time-frequency spectrum are totally same with those of the laser pulse absolute amplitude.

However, we note that, seen from Figs. 1(h) and 1(i), even though the harmonic cutoff energy can be largely extended, the HHG spectra exhibit more than five well-formed individual peak structures in the plateau region, which means that the plateau harmonics have more than ten quantum trajectories (five long trajectories and five short trajectories). If one select these plateau harmonics to synthesize an attosecond pulse, there're would have about ten individual peaks. That is an APT. However, people have been dedicated to obtain an IAP with short duration for many years [17, 26–29]. Therefore, if the plateau harmonic's quantum trajectory number is reduced, an APT with less peaks even an IAP may be generated. In the following, a nonlinear chirped frequency is introduced to the driving laser pulse and is expected to reduce the trajectory number.

3.1.2. introduce of the chirp

The chirp chosen is with a hyperbolic tangent form [18], and the time-dependent carrier envelope phase $\varphi(t)$ in Eq. (3) is then written as:

$$\varphi(t) = -\eta \tanh[(t - t_d)/\tau_c]. \quad (17)$$

Where τ_c is the steepness of the chirp function and t_d is set at the middle of the sweep here. η denotes the frequency sweeping range. If $\eta = 0$, driving pulse is chirp free.

With a chirp, as shown in Fig. 2(a), the laser pulse's temporal shape changes significantly to the pulse without chirp, and its origin oscillatory periodicity and up-down symmetry disappear: the central part of the carrier wave gets broader, the side parts become weaker, while the peak amplitude is remained. Importantly, the introduce of chirp makes the absolute amplitude difference between the pulse central peak and its neighbored ones get larger. According to the rapid level crossing theory, the time-frequency HHG spectrum shares the same shape with the absolute laser pulse amplitude [25]. Therefore, if the initial permanent dipole moment ξ is negative, it's easy to speculate that the HHG spectrum would have a large plateau whose harmonics have only two quantum trajectories at most. This trajectory number is much less than that of the case without chirp shown in Figs. 1(h) and 1(i). Thus, an APT with only two peaks can be synthesized using these plateau harmonics. However, it can be seen from Fig. 2(a) that, the introduce of chirp has weakened steepness of the laser pulse peak's rising and falling edges because of the increase of time interval between the peak time and its adjacent zero time which results from the getting broader of the center carrier. As mentioned before, the time-frequency HHG spectrum shares the same shape with the laser pulse absolute amplitude. Therefore, this

steepness weakening could lead to the enlargement of atto-chirp [30–32] for both long and short quantum trajectories, and this can increase the FWHM for both peaks of generated APT. However, it is contradictory for the center carrier to get narrower and for the absolute amplitude difference between the pulse central peak and its neighbored ones to get larger. Thus, a proper group of chirp parameters are chosen here as $\eta = 6.25$, $\tau_c = 120$, which can make the absolute amplitude difference quite large and the center carrier not too broad, just as shown in Fig. 2(a).

Fig. 2. (a) The laser pulse with and without chirped frequency, (b) the corresponding HHG spectrum from the driven-two-level polar medium [$\mu_{11} = 4$, $\mu_{22} = -4(\xi = -4)$], and (c) the wavelet time-frequency analysis. The lower panel of figure (c) shows time-dependent energy separation between the two dressed states $\epsilon_+ - \epsilon_-$ (the harmonic energy predicted by two-level model) as in Figs. 1(g), 1(h) and 1(i). The chirp parameters are: $\eta = 6.25$, $\tau_c = 120$. The other laser and two-level polar medium parameters are same with those in Fig. 1.

Fig. 2(b) shows the HHG spectrum of the two-level polar medium [$\mu_{11} = 4$, $\mu_{22} = -4(\xi = -4)$] driven by a chirped laser pulse. Compared to the case shown in Fig. 1(b) the only difference is the introduce of the chirp. Its corresponding time-frequency profile of the harmonic spectrum is shown in Fig. 2(c). Since the initial permanent dipole moment is negative, the cut-off harmonic should emit at peak time of the laser pulse. In addition, the introduce of chirp doesn't change the laser pulse envelope (E_0 and Ω_0 remain invariant). According to Eq. 16, the harmonic spectra should have the same cutoff energy as the case shown in Fig. 1(h). This is confirmed by the numerical results in Figs. 2(b) and 2(c). Because of the pulse shape changes mentioned before, there are only three well-formed individual peak structures besides the central peak in the time-frequency spectrum while the case without chirp has six ones. Moreover, these peak values are much smaller than those of case without chirp, this makes the value difference between the central peak and the sub-peak much larger than that of case without chirp shown in Fig. 1(h). Therefore, within a large plateau region, the harmonics would have two quantum trajectories. Therefore, one can use harmonics within this region to synthesize an APT with only two individual peaks.

Then, the plateau harmonics generated from the polar system [$\mu_{11} = 4$, $\mu_{22} = -4(\xi = -4)$] will be selected to synthesize attosecond pulses for both cases with and without chirp. All the harmonics (including the even orders) from 14th to 29th are selected for both cases. The results are shown in Figs. 3(a) and 3(b), respectively. Every FWHM value of all peaks is marked in the figures. There is an APT generated with ten individual peaks for the case without chirp, while there is an APT generated which has only two individual peaks (we call it attosecond pulse pair, APP). This is completely consistent with the quantum trajectory numbers in the plateau region (shown in Figs. 1(h) and 2(c)). Therefore, we have successfully reduced the individual peak numbers of the generated APT by introducing chirp frequency to the driving laser pulse. However, there is no an IAP generated. In addition, as shown in Fig. 3(b), the increase of FWHMs for both two center peaks confirms that the chirp frequency could enlarge the atto-chirp.

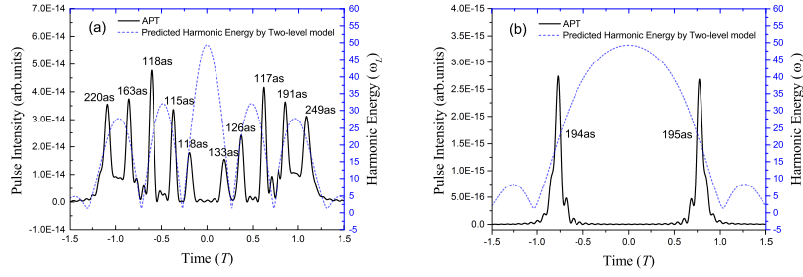

Fig. 3. Generated (a) attosecond pulse train (APT) for without chirp case and (b) attosecond pulse pair (APP) for with chirp case by synthesizing plateau harmonics (from 14th to 29th) of driven two-level polar medium. The other laser and two-level polar medium parameters are same with those in Fig. 2. The blue dashed curve is the harmonic energy predicted by the two-level model ($\epsilon_+ - \epsilon_-$) same with Fig. 2(c).

Thus we have demonstrated that the combination of controls, introduce of permanent dipole moment to two-level system and chirp frequency to driving laser pulse, has big influences on the HHG and attosecond pulse generation process. Due to the permanent dipole moment, much more plateau harmonics are generated and can be used to synthesize a shorter attosecond pulse; on the other hand, the chirp frequency could reduce the quantum trajectory numbers of plateau harmonics to a minimum of two which can finally lead to an APP generated. However, the pulse intensity is much weaker than that of the case without chirp (seen in Fig. 3). In view of this, a method that could enhance the harmonic signal intensity should be proposed to make up the intensity loss for introducing the chirp frequency. Here, we will investigate the propagation conditions and expect it can enhance the harmonic intensity.

3.2. propagation situation

Except considering the medium relaxation time, the other medium and all the laser parameters are all the same with those of non-propagation cases as in Fig. 3. Initial condition of the laser pulse was given in part *theoretical models and methods*.

Nineteen groups of propagation distance are investigated from 0 to 180 μm evenly divided by 10 μm , and harmonic generation in the transmission interface will be studied, respectively. The simulation results are shown in Fig. 4, including the HHG spectra, generated APPs, and the APP durations. The same plateau harmonic orders (14th to 29th) are selected to synthesize the APP as Fig. 3(b). The HHG spectra demonstrated that the propagation distance has a big influence on the plateau harmonic intensity. However the intensity is not linearly changed with propagation distance. The inset in Fig. 4(a) shows that at first the plateau harmonic intensity gradually increase to a maximum value, then decrease to a minimum value, after that it will process another increase and decrease process and so on. This process can be verified in Fig. 4(b) which clearly shows that the generated APP's intensity oscillates with propagation distance change. In our simulations, the maximum values appear at 60 μm and 130 μm . They are about ten times that of the non-propagation case. The duration is studied for two peaks of each APP, and it also changes with propagation distance variation. The change range is about 140as from 170as to 310as in our simulations. The minimum duration value 170as appears at about 120 μm . We note that, for distances 60 μm and 130 μm , their pulse peaks durations have an average about 220as which is not much longer than that of the non-propagation case. Therefore, we demonstrated that it can dramatically enhance the plateau harmonic intensity if propagates a suitable distance

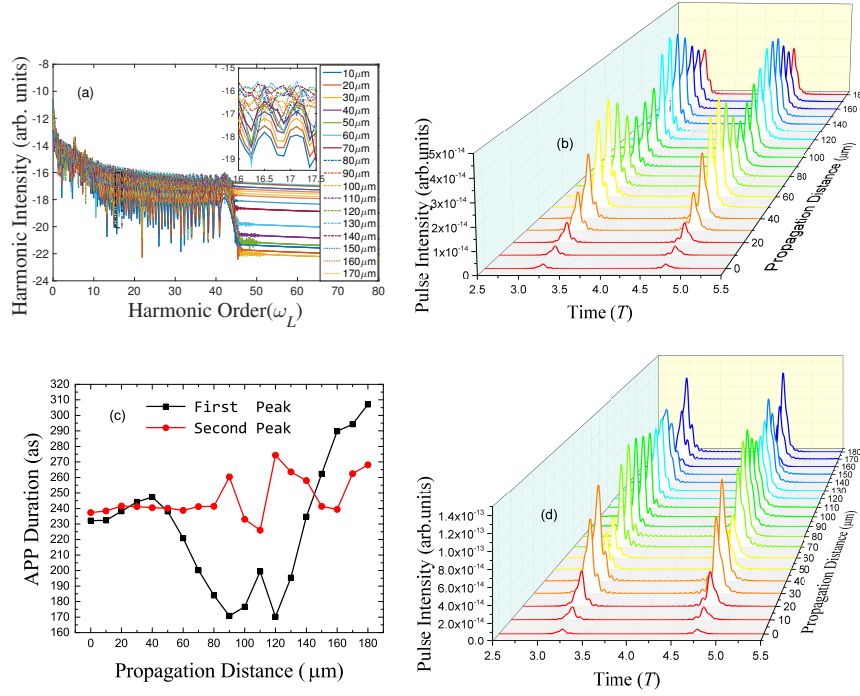

Fig. 4. (a) HHG spectra after different propagation distances. (b) Generated APPs by synthesizing plateau harmonics (between 14th to 29th) of spectra (a). (c) APP duration in a function of propagation distance. (d) Same as that in (b) but with a larger media density of $\bar{N} = 12.5 \times 10^{24} \text{m}^{-3}$. Two-level system has a permanent dipole moment of $\mu_{11} = 4$, $\mu_{22} = -4$ ($\xi = -4$). The other parameters are same with those of Fig. 3.

in the media. In addition to this, the medium density is also studied. We increased it to $\bar{N} = 12.5 \times 10^{24} \text{m}^{-3}$, and the corresponding APPs are shown in Fig. 4(d). It shows that the maximum intensity values appear at about 40 μm , 90 μm and 140 μm . The distance between adjacent is about 50 μm . It is about 20 μm less than that of the case of smaller media density $\bar{N} = 7.5 \times 10^{24} \text{m}^{-3}$. Therefore, one can enhance the harmonic intensity by using dense media to propagate a shorter distance or using sparse media to propagate a longer distance.

4. Conclusions

In this paper, we tried to combine the control of the matter and the control of the driving laser pulse to produce a high-order harmonic spectrum with a higher cutoff energy. It is shown that the existence of the permanent dipole moments can significantly extend the plateau of the harmonic spectrum. However, the plateau harmonic has more than two quantum trajectories, which can not generate an IAP by synthesizing harmonics within this region. If the laser pulse is chirped, the up-down symmetry of the laser field will be dramatically changed. This kind of laser pulse can exactly reduce the trajectory number to a minimum of two. Even though there's still no an IAP generated, an APT with only two individual peaks (APP) is obtained. If the propagation effect is considered, it can dramatically enhance the plateau harmonic intensity (maximum by one order) for a suitable propagation distance.
